

Entrenched Inflation Update for 9/24

J. Huston McCulloch

Nov. 14, 2024

Executive Summary

Entrenched inflation is now down to 3.05%. This warrants a Federal Funds Rate target of 4.07%.

Entrenched Inflation

With the Oct. 31 release of the Sept. 2024 PCE-PI, the univariate AR(1) Adaptive Least Squares (ALS) forecast of long-run entrenched inflation is now 3.05%, up imperceptibly from 3.04% last month, but substantially down from 3.52% as recently as last April.

Entrenched inflation is plotted in blue in Figure 1 below, along with year-over-year inflation in red. It was consistently over 4.00% throughout 12/21 – 4/23, warranting a Fed Funds rate of at least 5.50% throughout that period. However, entrenched inflation was only twice above 4.57 % during that period, despite year-over-year inflation that exceeded 6.00% throughout 12/21 – 8/22 and even touched on 7.00%. It has consistently been 3.60% or less ever since 10/23, warranting a rate of no more than 4.90% since that time. Its latest value of 3.05% currently warrants a Fed Funds Rate of 4.07%.

Figure 1

Entrenched (blue) and year-over-year (red) PCE Inflation

ALS is my refinement the Recursive Least Squares (RLS) estimator advocated by Sargent (1993, 1999) and by Evans and Honkapohja (2001). It can parsimoniously estimate

a general linear regression with time-varying parameters. See McCulloch (2024) below for details and references. In that paper I find that a simple model of monthly PCE inflation with a time-varying constant and no autoregressive parameters, as in the Adaptive Expectations model of Phillip Cagan (1956) and John Muth (1960), can be globally rejected in favor of a model with time-varying AR(1) transients. However, AR(1) cannot be rejected in favor of AR(2), AR(3), or AR(4). The likelihood-maximizing noise/signal ratio implies an asymptotic average lag of 21.7 months, using PCE-PI experience back to 1/59.

Since YoY inflation has an average lag of only 6 months, much of the variation in it is indeed “transitory.” It consistently overestimated entrenched inflation from early 2021 through early 2023. However, it has consistently underestimated entrenched inflation since that time.

The Taylor Rule

The above Fed Funds Rate recommendations are based on a “Taylor Rule” with a 2.0% inflation target, 150% feedback from expected inflation to interest rates, and a 0.5% “natural” real interest rate, while setting aside the unemployment gap.

Empirical Taylor Rules often find that the FOMC has placed a large coefficient on the lagged policy rate itself. However, the ALS estimate of entrenched inflation already optimally balances the newest information with the old information that went into earlier policy rates, so that adding the lagged policy rate would only unnecessarily lengthen the “Implementation Lag” portion of the already excessive Friedman-Schwartz “Inside Lag” in monetary policy.

Unlike now obsolete Adaptive Expectations, the AR(1) ALS model gives a different inflation forecast at each horizon, as shown in Figure 2 below, thus giving any Taylor rule a menu of possible policy horizons to work with. For example, the observed 9/24 month-over-month annualized inflation rate of 2.10%, as shown by the green star, predicts 2.61% inflation over the coming month, 2.82% on average over the coming 3 months, and 2.98% over the coming year, as shown by the blue line in the figure. However, *marginal* month-over-month predicted inflation, as shown by the red line, rises much more quickly toward its asymptotic value of 3.05%, and already exceeds 3.00% by 1/25. Furthermore, by the time the 9/24 PCE-PI was announced, 10/24 was already history and could no longer be affected by Fed policy. Since the FOMC only meets 8 times a year, another six weeks might also go by before it even meets. It therefore is appropriate, for Taylor Rule policy purposes, to look beyond the transitory first few months, and to focus instead on the more

entrenched forecasts farther into the future. While a forward forecast of annual inflation beginning say 3 months into the future could easily be constructed, in most cases the long-run asymptotic forecast would give virtually equivalent results.

Figure 2

Predicted average (blue) and marginal (red) inflation from 8/24

The best single predictor of future inflation is past inflation itself. Indeed, John Taylor's original 1993 paper simply used the most recent year-over-year inflation as its proxy for inflationary expectations. It is not inconceivable that other observed variables, such as unemployment or even interest rates themselves, have supplementary predictive power, and ALS could easily estimate a Vector Autoregression (VAR) that incorporates such variables. I plan to investigate that option in the future.

I plan to update this memo's entrenched inflation estimates monthly.
