A molecular beam electric resonance spectrometer has been used to observe pure hyperfine transistions of all four isotopic forms of rubidium chloride, with a linewidth of about 150 Hz. So far 179 observed lines have been identified as belonging to $^{85}Rb^{35}Cl$, and tentatively fitted to determine the hyperfine constants, including nuclear quadrupole and spin-rotation interactions for both nuclei, and the tensor and scalar spin-spin interactions, for vibrational states $v = 0 - 3$ and rotational states $J = 1 - 6$. An additional 103 lines have been identified and fitted for $^{87}Rb^{35}Cl$. The possibilities of a rubidium nuclear octupole interaction, and (in the case of ^{85}Rb) a nuclear electric hexadecapole interaction, are also being considered.
