Absorption lines from the molecules OH<sup>+</sup>, H<sub>2</sub>O<sup>+</sup>, and H<sub>3</sub><sup>+</sup> have all been observed in a diffuse molecular cloud along a line of sight near W51 IRS2. We present the first chemical analysis that combines the information provided by all three of these species. Together, OH<sup>+</sup> and H<sub>2</sub>O<sup>+</sup> are used to determine the molecular hydrogen fraction ( $f_{\text{H}_2}$ ) in the outskirts of the observed cloud, as well as the product of the cosmic-ray ionization rate of atomic hydrogen and an efficiency factor ( $\epsilon\zeta_{\text{H}}$ ). The efficiency factor ( $\epsilon$ ) describes what fraction of the time ionization of H by cosmic rays eventually leads to OH<sup>+</sup>. H<sub>3</sub><sup>+</sup> is used to infer the cosmic-ray ionization rate of H<sub>2</sub> ( $\zeta_2$ ) in the molecular interior of the cloud. By demanding that the two ionization rates are equal, and taking the value inferred from H<sub>3</sub><sup>+</sup> to be correct, we determine  $\epsilon$ . This is an important step in the future use of OH<sup>+</sup> and H<sub>2</sub>O<sup>+</sup> on their own as tracers of the cosmic-ray ionization rate.
